Abstract

Random variate generation is an important tool in statistical computing. Many programs for simulation or statistical computing (e.g. R) provide a collection of random variate generators for many standard distributions. However, as statistical modeling has become more sophisticated there is demand for larger classes of distributions. Adding generators for newly required distribution seems not to be the solution to this problem. Instead so called automatic (or black-box) methods have been developed in the last decade for sampling from fairly large classes of distributions with a single piece of code. For such algorithms a data about the distributions must be given; typically the density function (or probability mass function), and (maybe) the (approximate) location of the mode. In this contribution we show how such algorithms work and suggest an interface for R as an example of a statistical library.

1 Introduction

Random variate generation is an important tool in statistical computing. Many programs for simulation or statistical computing (e.g. R) provide a collection of random variate generators for many standard distributions. There exists a vast literature on generation methods for standard distributions; see, for example, the books by Devroye [4], Dagpunar [3], Gentle [5], or Knuth [8]. These books are usually the source for algorithms implemented in software. These algorithms are often especially designed for a particular distribution and tailored to the features of each probability density function. The designing goals for these methods are fast
generators and/or simple code. However, as statistical modeling has become more sophisticated there is demand for larger classes of (non-standard) distributions. Adding generators for newly required distribution seems not to be the solution to this problem.

In the last decade so called automatic (also called universal or black-box) methods have been developed for sampling from fairly large classes of distributions with a single piece of code. For such algorithms a data about the distributions must be given; typically the density function (or probability mass function), and (maybe) the (approximate) location of the mode. Obviously these universal methods need some setup step, in opposition to special generators, e.g., to the Box-Muller method [2]. Nevertheless, we always can select between a fast setup step and slow marginal generation times or (very) fast marginal generation times at the expense of a time consuming setup step. Some of the algorithms can be adjusted by a single parameter to the needs of the current situation. Although originally motivated to generate from non-standard distributions these universal methods have advantages which makes their usage attractive even for standard distributions. For univariate continuous distribution there are methods like Transformed Density Rejection [6], or algorithms based on a variant of the ratio-of-uniforms method [9] or on piecewise constant hat functions [1]. They have the following properties in common [see 10, for details]:

- Only one piece of code, well implemented and debugged only once, is required.
- By a simple parameter it is possible to choose between fast setup with slow marginal generation time and vice versa.
- It can sample from truncated distributions.
- The algorithms can be made as close to inversion as requested. Then:
  - The marginal generation time does not depend on the density function and is faster than many of the specialized generators (even for the normal distribution).
  - It can be used for variance reduction techniques.
  - The quality of the generated random numbers only depends on the underlying uniform random number generator.

For more details on these and many other universal methods see the forthcoming monograph by Hörmann, Leydold, and Derflinger [7].

2 UNU.RAN

Universal methods are usually harder to implement since there is a setup step where the necessary constants for the generation steps have to be precomputed. Moreover, it might be necessary whether a particular method works with the given distribution. Thus we have implemented many of these automatic algorithms using ANSI C in a library called UNU.RAN (Universal Non-uniform RANdom variate generators).
Our main goal was to get a portable, flexible and robust program, see Leydold et al. [11]. It is implemented using an object oriented programming paradigm. Using this library first a generator object has to be created that then can be used to sample from the given distribution. Thus it is easy to exchanged distributions in simulations. Moreover each generator object may have its own pseudo-random number generator or share one with other generators.

There exist two application programming interfaces: A “traditional” API where the generator object is created via new call and where replacement functions are used to replace default parameters by user defined. A second interface uses a string which describes both the desired distribution and the choosen generation method.

3 An R interface

We have propose an R interface for this library, called Runuran. This extends the usual functionality in R for random variate generation in several ways. First it is easy to sample from non-standard distributions. Secondly it is possible to choose different methods for a particular distribution, which is not possible in R yet except for normal distributions.

The object oriented approach of UNU.RAN is reproduced using S4 classes. This provides nearly all features of UNU.RAN and is very simple to use. In the following chapter we will describe the main ideas of our implementation and give example how to use UNU.RAN in R.

As we can see in the following simple example it is very easy to create non uniform random numbers for complicate distributions,e.g. the hyperbolic distribution:

```r
> hyp = new("unur","cont;pdf="1/sqrt(1+x^-2) *exp(-2*sqrt(1+x^-2) +x)"")
> x<-sample.unur(hyp,10000)
> hist(x,breaks=50)
```

Besides this default string interface of UNU.RAN there is also second interface available with several strings. The first one describe the distribution the second the method and the third one the parameters of the method.

```r
> gen = new("unur",distr="normal () ;domain=(0,inf)",
            method="arou", methodpars="max_sqhratio=0.9"")
> x<-sample.unur(gen,10000)
> hist(x,breaks=50)
```

The default values are the empty strings. The default methods depends on the distribution and is documented in [12]. We define in R an special S4-class named unur with two slots

```r
> setClass("unur",representation(string="character",p="externalptr"),
    prototype = list(string=character (), p="externalptr"))
```

In the slot string we save all necessary information about the distribution, used method etc. to generate our ‘generator object’ in UNU.RAN. A full description you
find in Leydold et al. [11], The second slot contains an external pointer which refer to a generator object created by UNU.RAN.

With the definition of function initialize for our class unur we ensure that after the creation of a new instance of the class unur we have a pointer to the generation object created and handed by the C-Code of UNU.RAN.

```r
> setMethod("initialize","unur",
function(.Object,x=character())
{
  ...    
  .Object@p <- .Call("R_unur_init",x)
  .Object
}
)
```

The user does not need to know anything about this object unless that it contains all information to create the random variates very fast and efficient. Of course UNU.RAN allocate memory which should be deallocate in R. R provides an ideal function named R_RegisterCFinalizer which ensure that the memory will be deallocated with the command gc().

Our first version uses only the same built in uniform RNG for all generators although UNU.RAN can uses multiple streams of uniform random number generators. With the functions

```r
> seed.unur(1234)
> reset.unur()
```

we can set and reset the seed.

The following examples should show some interesting features of our interface. We can use different algorithms for a large class of distributions

```r
> gen = new("unur",distr="beta()");method="tdr")
> x<-sample.unur(gen,10000)
```

or we can sample from truncated functions

```r
> gen = new("unur",distr="normal()");domain=(-1,1)"
> x<-sample.unur(gen,10000)
```

or we can sample from a kernel density estimate with kernel smoothing

```r
> gen = new("unur",distr="empk;data=(-0.1,0.05,....)",
method="empk", methodpars="smoothing=0.8")
> x<-sample.unur(gen,10000)
```

### 4 Conclusion

Our interface provides the possibility to use a lot of algorithms in R to generate non uniform variates for large classes of distributions. Due to the implementation
of S4-classes the handling is very easy. A R package with automatic installation and
documentation is in preparation. A closer relationship between R and UNU.RAN
would be possible and easy to realize. For example to define a distribution function
in R and use algorithms of UNU.RAN to generate random numbers. But this make
only sense if we would first define an distribution object in R. This is already in
planning by a group in Bayreuth [12]. A lot of contributed packages of R use random
numbers of special distributions but everybody use his own code and variables.
Therefore we think that a standard description of distribution objects including
generation of random numbers would be helpful for a lot of code developers in R.
